On Structural Descriptions of Lower Ideals of Series Parallel Posets

Christian Joseph Altomare[1]

The Ohio State University, 231, West 18th Avenue, Columbus, Ohio, United States

Abstract

In this paper we give an algorithm to determine, for any given suborder closed class of series-parallel posets, a structure theorem for the class. We refer to these structure theorems as structural descriptions.

1. Introduction

1.1. Background

Many important theorems in combinatorics characterize a class by forbidden subobjects of some kind. This is a description of the class "from the outside", by what is not inside it. An example is Wagner's reformulation [9] of Kuratowski's Theorem [3] stating that a graph is planar iff it has no K_5 minor and no $K_{3,3}$ minor. To be a good characterization, the list of forbidden objects should be finite. Well quasi order theorems such as the Graph Minor Theorem [6] state that for certain classes of objects, there is always such a finite description "from the outside".

Just as important are those theorems that characterize a class "from the inside" by giving some set of starting objects and some set of construction rules. As a simple example, consider (graph theoretic) trees. Each tree is either a single point graph or may be obtained from two smaller, disjoint trees by adding an edge between the trees. Therefore a simple structure theorem for this

Email address: caltomare@towson.edu (Christian Joseph Altomare)

class would have the single point graph as the only starting graph and joining two disjoint graphs by an edge as the sole construction rule.

To be a good characterization, we again hope that it is in some sense finite. First, there should be only finitely many construction rules. We can not necessarily demand there are only finitely many starting objects. We may however demand that at least we start with only finitely many families, and that each such family has some sort of finite description as well.

Analogous to the Graph Minor Theorem and other well quasi order theorems stating that in many cases there is always a finite description from the outside, it was asked if it could be shown in an equally general setting that there is always a finite description from the inside with finitely many starting families, each itself finitely described, and finitely many construction rules.

As it turns out, this appears to be far more difficult. This line of research was first pursued by Robertson, Seymour, and Thomas in [7] for trees under the topological minor relation. In [5], Nigussie and Robertson build on [7] and correct some technical errors contained therein. In [4], Nigussie gives an algorithm that finds a structure theorem for an arbitrary topological minor closed property of trees. Nigussie's algorithm is efficient enough in practice that structure theorems can be computed by hand with pen and paper that are not at all obvious without the algorithm. We follow the convention of referring to these structure theorems as structural descriptions. The distinction we make is that we use the term structure theorem informally, while we see structural description as a technical term defined in [4] for trees under topological minor and below for series-parallel orders under suborder.

Attempts have been made by various researchers to generalize these results to other classes of graphs, in particular series-parallel graphs. Thus far, no such attempt has succeeded. While many specific graph structure theorems are known, the tree result is to date the only one that allows the automatic computation of a structure theorem for any graph property in a nontrivial, infinite class of properties.

It is key that rooted trees are used in [7], [5], and [4]. Rooted trees are as

much partial orders as they are graphs, and we view Nigussie's algorithm not just as a graph algorithm, but as a partial order algorithm. It is thus natural to ask for algorithms similar to Nigussie's for classes of partial orders larger than the class of trees. In this paper, we prove an analogous result for series-parallel partial orders by giving a finite structural description for each suborder closed class of series-parallel orders. More precisely, we give an algorithm that takes as input a suborder closed class of series-parallel orders described by forbidden suborders, and which gives as output a finite structural description for that class.

In our context, a structural description will turn out to be a finite set of labeled partial orders. The labels will be families already constructed. Each labeled partial order in the structural description for a class will represent one family or construction rule. Roughly, the labels tell what we are allowed to put in and the partial orders themselves tell us how we are allowed to piece together what we do put in.

2. Basic Definitions and Conventions

A partial order is a (possibly empty) set P together with a reflexive, antisymmetric, transitive binary relation $\leq$ on P. All partial orders in this paper are assumed to be finite. (The only exception to this is that *classes of* partial orders we consider are usually infinite, and this class together with the suborder relation is in fact a partial order. This exception causes no confusion as it is clear in each case whether we are dealing with a partial order or an infinite family of them.) Points x, y in a partial order $(P, \leq)$ are comparable if $x \leq y$ or $y \leq x$. Otherwise x and y are called incomparable, which we write as $x|y$. A chain is a partial order such that any two points are comparable. An antichain is a partial order such that any two points are incomparable.

A lower ideal of partial orders is a family of partial orders that is closed under taking suborders. Given partial orders P and Q, we say that P is Q-free if P has no suborder isomorphic to Q. Given a set F of partial orders, we say that P is F-free if P is Q-free for each Q in F. A lower ideal L is said to be

Q-free or F-free if each partial order in L is Q-free or F-free, respectively. A forbidden suborder of a lower ideal L is a suborder minimal partial order P such that L is P-free.

The papers [7], [5], and [4] use tree sums to construct new trees from old. For our purposes, tree sums are not sufficient. The correct generalization to our context is partial order lexicographic sums. We call partial orders $(P_i, \leq_i)$ and $(P_j, \leq_j)$ disjoint if P_i and P_j are disjoint.

Definition 1. Let $\{(P_i, \leq_i)\}_{i \in I}$ be a family of pairwise disjoint partial orders and let $(I, \leq_I)$ be a partial order on I. Then the lexicographic sum $\bigoplus_{\leq_I} P_i$ is defined as the unique partial order $(\bigcup_{i \in I} P_i, \leq)$ such that the following conditions hold:

1. Given i in I and x and y in P_i, we have $x \leq y$ iff $x \leq_i y$.
2. Given distinct i, j in I, if $i \leq_I j$, then $x \leq y$ for all x in P_i and y in P_j.
3. Given distinct i, j in I, if i and j are $\leq_I$ incomparable, then x and y are $\leq$ incomparable for all x in P_i and y in P_j.

It is a simple exercise to show that the above three conditions indeed uniquely determine a partial order on $\bigcup_{i \in I} P_i$. We call $(I, \leq_I)$ the outer partial order of the lexicographic sum. Each P_i is called the inner partial order corresponding to i. The lexicographic sum is therefore a partial order on the union of the inner partial orders. We call the partition of $\bigoplus_{\leq_I} P_i$ into the inner partial orders P_i a lexicographic partition. It is simple to show that a partition of a partial order is lexicographic iff for any two distinct cells C_1 and C_2 of the partition, either all elements of C_1 precede all elements of C_2, all elements of C_2 precede all elements of C_1, or all elements of C_1 and C_2 are incomparable. In this case, the outer partial order is uniquely determined in the obvious way.

We call a lexicographic partition nontrivial if there are at least two cells and each cell is nonempty. We call a lexicographic partition a chain partition if the corresponding outer partial order is a chain. Similarly for antichain partitions. We call a lexicographic sum a chain sum or antichain sum if the corresponding partition is nontrivial and the outer partial order is a chain or antichain, respectively. We denote by $P_1 \prec \cdots \prec P_n$ the chain sum of partial orders $P_1, \ldots, P_n$ such that for $1 \leq i < j \leq n$, every x in P_i is less than every y in P_j. We denote

by $P_1 \oplus \cdots \oplus P_n$ the antichain sum of partial orders $P_1, \ldots, P_n$ such that for all $i \neq j$, every x in P_i is incomparable to every y in P_j.

The comparability graph of a partial order P is the graph whose vertices are the points of P and such that two points x and y are adjacent iff they are comparable in P. A component of P is a component of the comparability graph. An anticomponent is a component of the similarly defined incomparability graph. If P is a chain sum, we note that P then has a unique finest chain partition, which is just the partition into anticomponents. If $P = P_1 \prec \cdots \prec P_n$ and $\{P_1, \ldots, P_n\}$ is a finest chain partition with $n \geq 2$, then we call $P_1 \prec \cdots \prec P_n$ a finest chain representation of P. A similar statement holds for antichain sums and components, and we then similarly call $P_1 \bigoplus \cdots \bigoplus P_n$ a finest antichain representation of P for $n \geq 2$.

A partial order is a series-parallel partial order, or SP order, if it is contained in the smallest class of partial orders containing the empty and single point partial orders and closed under chain and antichain sums. We note that for each SP order P, exactly one of the following holds: P is empty, P is a single point, P is a chain sum, or P is an antichain sum. We will make use of the simple but important fact that a suborder of an SP order is also an SP order. It is also worth noting that a finite partial order is an SP order iff it is N-free, where N is the partial order on points a, b, c, d such that $a < b$, $b > c$, $c < d$, and all others pairs of points are incomparable [1], though we do not make use of this fact.

Since all our ideals in this paper are lower ideals of SP orders, from now on we simply call these lower ideals. A proper lower ideal is a lower ideal that is strictly contained in the set of all SP orders. A nontrivial lower ideal is one that contains at least one nonempty partial order. Our goal in this paper is to give a structural description for an arbitrary nontrivial, proper lower ideal. More precisely, we give a recursive procedure that takes as input a nontrivial, proper lower ideal, which gives as output a structural description for that lower ideal. This procedure is entirely constructive, and a program could be written to implement it, though algorithmic questions are not our focus.

A structural description, for us, will turn out to be a finite set of labeled SP orders. The labels tell us which objects we may use to construct, and the orders themselves tell us in which ways we may put these together. We now start to make this intuition more precise.

A labeled partial order is a triple $(I, \leq_I, f)$, where $(I, \leq_I)$ is a partial order and f is a function with domain I. We think of f as the labeling function. We sometimes write I_f for this labeled partial order when $\leq_I$ is clear from context. A bit is a labeled SP order such that each label is a lower ideal or the symbol R. We call a point i in a bit $(I, \leq_I, f)$ an ideal labeled point if $f(i)$ is a lower ideal. We call i an R labeled point if $f(i) = R$. A recursive bit is a bit with at least one R labeled point. A nonrecursive bit is a bit with no R labeled points. The two point chain with both points labeled R is denoted by R_C. The two point antichain with both points labeled R is denoted by R_A.

We now tell how to assign to each set S of bits the lower ideal $L(S)$ that S is said to generate. Given a set S of bits and a set X of partial orders, we say that X is S-bit closed if X contains all lexicographic sums of the form $\bigoplus_{\leq_I} P_i$ such that $(I, \leq_I, f)$ is a bit in S, the partial order P_i is contained in the lower ideal $f(i)$ for each ideal labeled point i in I, and P_i is contained in X itself for each R labeled point i in I. The S-bit closure of X is the smallest S-bit closed set containing X. Given a set S of bits, we define the lower ideal $L(S)$ generated by S as the S-bit closure of the set containing the empty partial order, the one point partial order, and no other partial orders.

Given a bit $(I, \leq_I, f)$, we say that X is $(I, \leq_I, f)$-bit closed if X is $\{(I, \leq_I, f)\}$-bit closed. We will have many occasions to use the following simple lemma, whose proof is immediate from the definition.

Lemma 2. *If S is a set of bits and X is a set of partial orders, then X is S-bit closed iff X is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in S.*

We now define structural descriptions. We do so by recursively defining structural descriptions of each nonnegative integer *rank*. The empty set, thought of as an empty set of bits, is the only structural description of rank 0. Assume

the structural descriptions of ranks $0, \dots, n$ are known. A structural description of rank $n+1$ is a finite set S of finite, labeled SP orders such that each label of each bit in S is either the special symbol "R" or a structural description of rank at most n. A structural description is a structural description of some finite rank. Note that since we require finiteness at each step, each of our structural descriptions would be considered a "finite structural description" in the informal sense of the term.

A structural description D generates a lower ideal $L(D)$ analogously to the previous definition for bits. We say this is a structural description *for* $L(D)$ or *of* $L(D)$.

Our recursive procedure will take a lower ideal as input and give a finite structural description as output. We just made precise what form the output takes. To state the form of the input, we first need several definitions. A quasi order is a set Q together with a transitive, reflexive relation $\leq$. A quasi order is a well quasi order, or WQO, if for all infinite sequences $q_1, q_2, \dots$ of points in Q, there are positive integers $i < j$ such that $q_i \leq q_j$. A class $\mathcal{C}$ of partial orders is then said to be well quasi ordered under suborder if for each infinite sequence $(P_1, \leq_1), (P_2, \leq_2), \dots$, of partial orders in $\mathcal{C}$, there are positive integers $i < j$ such that $(P_i, \leq_i)$ is a suborder of $(P_j, \leq_j)$.

Given an SP order P, we let $\mathrm{Forb}(P)$ be the set of SP orders forbidding P as a suborder. Given a set $F = \{Q_1, \dots, Q_k\}$ of SP orders, we denote the set of SP orders forbidding each P in F as a suborder by $\mathrm{Forb}(F)$ or $\mathrm{Forb}(Q_1, \dots, Q_k)$. It can be shown that finite SP orders form a WQO under the suborder relation. Basic WQO theory then implies that for each lower ideal L, there is a finite set F of SP orders such that $L = \mathrm{Forb}(F)$ [2]. With these facts stated, we may now express the main result of this paper more precisely; we give an algorithm that takes a finite set F of SP orders as input and outputs a structural description D such that $L(D) = \mathrm{Forb}(F)$.

Since our main focus is combinatorial structure theory, we do not concern ourselves with algorithmic or complexity theoretic questions. Though such questions may be interesting, they are simply not our focus here. We thus present

our algorithms in the same informal style that is common in mathematics.

3. Technical Lemmas

We note that the reader familiar with SP orders can likely skim or skip much of this section. Even readers unfamiliar with SP orders may find it useful to proceed to the next section and refer back to this section as needed.

We call an SP order connected if its comparability graph is connected. An SP order is anticonnected if its incomparability graph is connected.

Lemma 3. *Every chain sum is connected. Similarly, every antichain sum is anticonnected.*

PROOF. Let $P_1 \prec \cdots \prec P_n$ be a chain sum. By definition, we can assume without loss of generality that $n \geq 2$ and each P_i is nonempty. For $i \neq j$, each point x of P_i is comparable to each point y in P_j and hence x and y are adjacent in the comparability graph. If two points x and y are contained in the same P_i, then choose $i \neq j$ and z in P_j. Then x and y are both adjacent to z and hence in the same component. Therefore given any points x and y in $P_1 \prec \cdots \prec P_n$, there is a path of length one or two between x and y in the comparability graph of P, and the first claim of the lemma holds. For the second claim, repeat the same proof with $P_1 \bigoplus \cdots \bigoplus P_n$ and the incomparability graph.

Lemma 4. *Each component of $P_1 \bigoplus \cdots \bigoplus P_n$ is contained in some P_i. Each anticomponent of $P_1 \prec \cdots \prec P_n$ is contained in some P_i.*

PROOF. A component of $P_1 \bigoplus \cdots \bigoplus P_n$ is connected in the comparability graph. Since there are no edges from P_i to P_j for $i \neq j$ in the comparability graph, we see that each component is contained in some P_i. The proof of the second claim is analogous.

Lemma 5. *If Q is a chain sum and P_i is Q-free for i in $\{1, \ldots, n\}$, then $P_1 \bigoplus \cdots \bigoplus P_n$ is Q-free.*

Proof. Let Q be a chain sum. It is enough to show that if $P_1 \bigoplus \cdots \bigoplus P_n$ contains Q, then P_i contains Q for some i. Since Q is a chain sum, we know by 3 that Q is connected. By 4, Q must therefore be contained in some P_i.

The next lemma is analogous to the previous lemma, and the same proof goes through mutatis mutandis.

Lemma 6. *If Q is an antichain sum and P_i is Q-free for i in $\{1, \ldots, n\}$, then $P_1 \prec \cdots \prec P_n$ is Q-free.*

We need several technical lemmas.

Lemma 7. *If $P_1 \prec \cdots \prec P_n$ is a finest chain representation of an SP order P, then each P_i is an antichain sum or a one point partial order.*

Proof. For each i, since P_i is a suborder of an SP order, P_i itself is an SP order. Since $P_1 \prec \cdots \prec P_n$ is a finest chain representation by hypothesis, it follows by definition of finest chain representation that P_i is not itself a chain sum, and P_i is therefore a single point or an antichain sum as claimed.

The same holds for finest antichain representations. We omit the entirely analogous proof.

Lemma 8. *If $P_1 \oplus \cdots \oplus P_n$ is a finest antichain representation of an SP order P, then each P_i is a chain sum or a one point partial order.*

Lemma 9. *Let $P_1 \oplus \cdots \oplus P_n$ be a finest antichain representation of a partial order P and let $Q_1 \oplus \cdots \oplus Q_k$ be an arbitrary antichain sum. If $P_1 \oplus \cdots \oplus P_n$ is a suborder of $Q_1 \oplus \cdots \oplus Q_k$, then for each i with $1 \leq i \leq n$ there is j with $1 \leq j \leq k$ such that P_i is a suborder of Q_j.*

Proof. Choose i. Note that P_i is a chain sum or a one point partial order by 8. If P_i is a single point, then P_i is of course contained in some Q_i. If P_i is a chain sum, then it is connected and therefore contained in a component of $Q_1 \oplus \cdots \oplus Q_k$. Since each component of $Q_1 \oplus \cdots \oplus Q_k$ is contained in some Q_i, the result follows.

The following lemma has a similar proof.

Lemma 10. *Let $P_1 \prec \cdots \prec P_n$ be a finest chain representation of a partial order P and let $Q_1 \prec \cdots \prec Q_k$ be an arbitrary chain sum. If $P_1 \prec \cdots \prec P_n$ is a suborder of $Q_1 \prec \cdots \prec Q_k$, then for each i with $1 \leq i \leq n$ there is j with $1 \leq j \leq k$ such that P_i is a suborder of Q_j.*

Lemma 11. *Let $P_1 \prec \cdots \prec P_n$ be a finest chain representation of an SP order P that is contained in the partial order $Q_1 \prec Q_2$. If the P_i of $P_1 \prec \cdots \prec P_n$ is contained in Q_1 then so is $P_1 \prec \cdots \prec P_i$. Similarly, if the P_i of $P_1 \prec \cdots \prec P_n$ is contained in Q_2 then so is $P_i \prec \cdots \prec P_n$.*

Proof. We prove the first claim. The second is similar. By hypothesis, the P_i of $P_1 \prec \cdots \prec P_n$ is a suborder of Q_1. Since every point of $P_1 \prec \cdots \prec P_i$ is less than or equal some point of P_i, and since Q_1 is a downward closed subset of $Q_1 \prec Q_2$ containing P_i, it follows that $P_1 \prec \cdots \prec P_i$ is a suborder of Q_1.

Lemma 12. *If $P_1 \prec \cdots \prec P_n$ is a finest chain representation that is contained in the partial order $Q_1 \prec Q_2$, then one of the following three conditions holds:*

1. *$P_1 \prec \cdots \prec P_n$ is a suborder of Q_1.*
2. *$P_1 \prec \cdots \prec P_n$ is a suborder of Q_2.*
3. *There is i with $1 \leq i < n$ such that $P_1 \prec \cdots \prec P_i$ is a suborder of Q_1 and $P_{i+1} \prec \cdots \prec P_n$ is a suborder of Q_2.*

Proof. Since $P_1 \prec \cdots \prec P_n$ is a finest chain representation by hypothesis, we know that each P_i is contained in Q_1 or Q_2 by 10. If $P_1 \prec \cdots \prec P_n$ is a suborder of Q_1 or Q_2 then we are done. Suppose not. Take the largest i such that P_i is a suborder of Q_1. By 11, we see that $P_1 \prec \cdots \prec P_i$ is a suborder of Q_1. Since $P_1 \prec \cdots \prec P_n$ is not a suborder of Q_1 by hypothesis, we know that $i < n$. Therefore P_{i+1} is a suborder of Q_2. Again by 11, we see that $P_{i+1} \prec \cdots \prec P_n$ is a suborder of Q_2, which completes the proof.

4. The Main Lemmas

Given labels $X_1, \ldots, X_n$, we let the notation $X_1 \prec \cdots \prec X_n$ denote the n point labeled chain with bottom point labeled X_1, next least point labeled X_2, and so on. Note that $P_1 \prec \cdots \prec P_n$ defined previously is the chain sum of n partial orders $P_1, \ldots, P_n$ (which is of course itself a partial order). On the other hand, $X_1 \prec \cdots \prec X_n$ denotes a labeled n point chain bit. As long as the reader keeps this distinction in mind, no confusion arises. Similarly for the expression $X_1 \oplus \cdots \oplus X_n$.

Definition 13. Let $n \geq 2$. The chain bit set $\mathrm{BS}(P)$ corresponding to a chain P with finest chain representation $P_1 \prec \cdots \prec P_n$ is defined to be the set of bits B such that one of the following conditions hold:

1. $B = R \prec \mathrm{Forb}(P_n)$.
2. $B = \mathrm{Forb}(P_1) \prec R$.
3. There is i with $1 < i < n$ such that

$$B = \mathrm{Forb}(P_1 \prec \cdots \prec P_i) \prec \mathrm{Forb}(P_i \prec \cdots \prec P_n)$$

We note that since the finest chain representation is uniquely determined, the notation $\mathrm{BS}(P)$ is well defined for chain sums P.

Lemma 14. *Let $n \geq 2$. If P is an SP order with finest chain representation $P_1 \prec \cdots \prec P_n$, then*

$$\mathit{Forb}(P_1 \prec \cdots \prec P_n) = L(\mathit{BS}(P) \cup \{R_A\}).$$

Proof. Let $S = \mathrm{BS}(P_1 \prec \cdots \prec P_n) \cup \{R_A\}$. We must show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is the S-bit closure of the doubleton containing the empty and one point partial orders. Since $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ trivially contains the empty and one point partial orders, it is enough to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is S-bit closed and that every S-bit closed set containing the empty and one point partial orders has $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ as a subset.

We first show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is S-bit closed. By 2, it is enough to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in S. We consider four cases.

First, if $(I, \leq_I, f)$ is R_A, then to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed is simply to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is closed under antichain sums. But this is exactly 5.

Second, if $(I, \leq_I, f)$ is a two point chain with bottom point labeled R and top point labeled $\mathrm{Forb}(P_n)$, then to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed is to show that if Q_1 is a partial order in $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ and Q_2 is a partial order in $\mathrm{Forb}(P_n)$, then $Q_1 \prec Q_2$ forbids $P_1 \prec \cdots \prec P_n$. Suppose not. Since $Q_1 \prec Q_2$ contains $P_1 \prec \cdots \prec P_n$, in particular $Q_1 \prec Q_2$ contains the top inner part P_n of the chain sum. By 10, we see that P_n is a suborder of Q_1 or Q_2. Since Q_2 forbids P_n, we know that P_n is a suborder of Q_1. By 11, it follows that $P_1 \prec \cdots \prec P_n$ is a suborder of Q_1, contrary to hypothesis. This contradiction shows that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed as claimed.

The third case, that $(I, \leq_I, f)$ is a two point chain with top point labeled R and bottom point labeled $\mathrm{Forb}(P_1)$, is completely analogous to the second case, and the proof goes through mutatis mutandis.

Fourth, if there is i with $1 < i < n$ such that $(I, \leq_I, f)$ is a two point chain with bottom point labeled $\mathrm{Forb}(P_1 \prec \cdots \prec P_i)$ and top point labeled $\mathrm{Forb}(P_i \prec \cdots \prec P_n)$, then to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed, we must show that if Q_1 is a partial order forbidding $P_1 \prec \cdots \prec P_i$ and Q_2 is a partial order forbidding $P_i \prec \cdots \prec P_n$, then $Q_1 \prec Q_2$ forbids $P_1 \prec \cdots \prec P_n$. We prove the contrapositive statement, namely, that if $Q_1 \prec Q_2$ has a $P_1 \prec \cdots \prec P_n$ suborder then Q_1 has a $P_1 \prec \cdots \prec P_i$ suborder or Q_2 has a $P_i \prec \cdots \prec P_n$ suborder. Since $P_1 \prec \cdots \prec P_n$ is a suborder of $Q_1 \prec Q_2$, in particular P_i is also. By 10, P_i is therefore a suborder of Q_1 or Q_2. By 11, if P_i is a suborder of Q_1 then $P_1 \prec \cdots \prec P_i$ is as well. 11 similarly implies that if P_i is a suborder of Q_2 then $P_i \prec \cdots \prec P_n$ is as also. The contrapositive is thus proved, which completes the proof that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed in this final case.

We now know that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is S-bit closed. Next, we show that every S-bit closed set X containing the empty and one point partial orders has

$\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ as a subset.

Suppose not. Then the S-bit closure X of the set containing the empty and one point partial orders is a proper subset of the S-bit closed set $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$. Take a minimum cardinality SP order Q in $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ that is not in X. Then Q has at least two elements by choice of X. Since Q is an SP order, it follows that Q is a chain or antichain sum.

If Q is an antichain sum, then we may write $Q = Q_1 \oplus Q_2$, where Q_1 and Q_2 each have fewer elements than Q. Since Q is a minimum size partial order in $\mathrm{Forb}(P_1 \prec \cdots \prec P_n) - X$ by hypothesis, we see that Q_1 and Q_2 are in X. Since X is $(I, \leq_I, f)$-bit closed for $(I, \leq_I, f)$ the two point antichain R_A with both points labeled R, it follows that the antichain sum of two orders in X is in X as well. In particular, Q is in X, contrary to hypothesis. This contradiction shows that Q can not be an antichain sum.

Since Q is not an antichain sum, Q must be a chain sum $Q = Q_1 \prec Q_2$. By choice of Q as minimal, we know that Q_1 and Q_2 are in X. Suppose Q_2 is in $\mathrm{Forb}(P_n)$. Since Q_1 is in X and Q_2 is in $\mathrm{Forb}(P_n)$, and since X is $(I, \leq_I, f)$-bit closed for $(I, \leq_I, f)$ the two point chain with top labeled $\mathrm{Forb}(P_n)$ and bottom labled R, we see that $Q_1 \prec Q_2$ must be in X, contrary to hypothesis. Therefore Q_2 is not in $\mathrm{Forb}(P_n)$. By similar reasoning, Q_1 is not in $\mathrm{Forb}(P_1)$.

Choose the least i such that Q_1 does not have a $P_1 \prec \cdots \prec P_i$ suborder. Then Q_1 has a $P_1 \prec \cdots \prec P_{i-1}$ suborder. If Q_2 has a $P_i \prec \cdots \prec P_n$ suborder, then $Q_1 \prec Q_2$ has a $P_1 \prec \cdots \prec P_n$ suborder, contrary to hypothesis. Therefore Q_2 has no $P_i \prec \cdots \prec P_n$ suborder. Therefore Q_1 is in $\mathrm{Forb}(P_1 \prec \cdots \prec P_i)$ and Q_2 is in $\mathrm{Forb}(P_i \prec \cdots \prec P_n)$. Since the two point chain with top labeled $\mathrm{Forb}(P_i \prec \cdots \prec P_n)$ and bottom labeled $\mathrm{Forb}(P_1 \prec \cdots \prec P_i)$ is a bit in S and X is S-bit closed, it follows that $Q_1 \prec Q_2 = Q$ is in X, contrary to hypothesis.

In all cases, the assumption that X is a proper subset of $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is a contradiction. Equality therefore holds, thus completing the proof.

To give a similar result for excluding a set of chain sums, we first need some definitions.

Definition 15. Fix $k \geq 1$. For $1 \leq i \leq k$ let P_i be a chain sum. A chain bit choice function for $(P_1, \ldots, P_k)$ is a function c mapping each P_i to a chain bit in $\mathrm{BS}(P_i)$.

Given a chain bit $(I, \leq_I, f)$, we let $\mathrm{Bottom}((I, \leq_I, f))$ and $\mathrm{Top}((I, \leq_I, f))$ denote the labels of the bottom and top points, respectively, of $(I, \leq_I, f)$.

In the next definition, we must intersect labels of bits. If all labels are ideals, then no comment is necessary, but in general some labels may be the symbol R, so we must extend the notion of intersection to include this symbol. We make the convention that in the definition of bit set corresponding to $(P_1, \ldots, P_k)$ below, the symbol R is taken to mean $\mathrm{Forb}(P_1, \ldots, P_k)$. In other words, the intersection of R with a set is the intersection of $\mathrm{Forb}(P_1, \ldots, P_k)$ and that set. Moreover, if a rule tells us that a point should be labeled $\mathrm{Forb}(P_1, \ldots, P_k)$, we label that point R. Without this convention, stating the following definition would be quite lengthy.

Definition 16. Fix $k \geq 1$. For $1 \leq i \leq k$, let P_i be a chain sum. The chain bit set $\mathrm{BS}(P_1, \ldots, P_k)$ corresponding to the tuple $(P_1, \ldots, P_k)$ is the set of two point chain bits of the form

$$\bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i)) \prec \bigcap_{1 \leq i \leq k} \mathrm{Top}(c(P_i)).$$

such that c is a chain bit choice function for $(P_1, \ldots, P_k)$.

We note that the previous definition is consistent with 13 for the case $k = 1$. The following lemma generalizes 14 to the case of excluding an arbitrary finite set of chain sums.

Lemma 17. *Let $k \geq 1$. If the SP orders $P_1, \ldots, P_k$ are chain sums, then*

$$\mathit{Forb}(P_1, \ldots, P_k) = L(\mathit{BS}(P_1, \ldots, P_k) \cup \{R_A\}).$$

Proof. For $k = 1$, this is just 14, so we assume without loss of generality that $k \geq 2$.

Let $S = \mathrm{BS}(P_1, \ldots, P_k) \cup \{R_A\}$. We must show that $\mathrm{Forb}(P_1, \ldots, P_k)$ is the S-bit closure of the doubleton containing the empty and one point partial

orders. Since $\mathrm{Forb}(P_1, \ldots, P_k)$ trivially contains the empty and one point partial orders, it is enough to show that $\mathrm{Forb}(P_1, \ldots, P_k)$ is S-bit closed and that every S-bit closed set containing the empty and one point partial orders has $\mathrm{Forb}(P_1, \ldots, P_k)$ as a subset.

We first show that $\mathrm{Forb}(P_1, \ldots, P_k)$ is S-bit closed. By 2, it is enough to show that $\mathrm{Forb}(P_1, \ldots, P_k)$ is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in S.

First, if $(I, \leq_I, f)$ is R_A, then to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is $(I, \leq_I, f)$-bit closed is simply to show that $\mathrm{Forb}(P_1 \prec \cdots \prec P_n)$ is closed under antichain sums. But this is exactly 5.

If $(I, \leq_I, f) \neq R_A$, then $(I, \leq_I, f)$ has the form

$$\bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i)) \prec \bigcap_{1 \leq i \leq k} \mathrm{Top}(c(P_i))$$

for some chain bit choice function c for $(P_1, \ldots, P_k)$. To show that $\mathrm{Forb}(P_1, \ldots, P_k)$ is $(I, \leq_I, f)$-bit closed is thus to show that for each chain bit choice function c for $(P_1, \ldots, P_k)$, if Q_1 and Q_2 are SP orders in $\mathrm{Forb}(P_1, \ldots, P_k)$ such that Q_1 is in $\bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i))$ and Q_2 is in $\bigcap_{1 \leq i \leq k} \mathrm{Top}(c(P_i))$, then $Q_1 \prec Q_2$ is in $\mathrm{Forb}(P_1, \ldots, P_k)$ as well. To show that $Q_1 \prec Q_2$ is in $\mathrm{Forb}(P_1, \ldots, P_k)$, we must show that $Q_1 \prec Q_2$ forbids P_i for $1 \leq i \leq k$, so choose i. Since Q_1 is in $\bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i))$, in particular Q_1 is in $\mathrm{Bottom}(c(P_i))$. Similarly Q_2 is in $\mathrm{Top}(c(P_i))$. Since c is a chain bit choice function for $(P_1, \ldots, P_k)$, we see that $\mathrm{Bottom}(c(P_i)) \prec \mathrm{Top}(c(P_i))$ is a chain bit in $\mathrm{BS}(P_i)$. Both Q_1 and Q_2 are in $\mathrm{Forb}(P_i)$. Therefore $Q_1 \prec Q_2$ is in $\mathrm{Forb}(P_i)$ as needed. This completes the proof that $\mathrm{Forb}(P_1, \ldots, P_k)$ is S-bit closed.

We now know that $\mathrm{Forb}(P_1, \ldots, P_k)$ is S-bit closed. Next, we show that every S-bit closed set X containing the empty and one point partial orders has $\mathrm{Forb}(P_1, \ldots, P_k)$ as a subset.

Suppose not. Then the S-bit closure X of the set containing the empty and one point partial orders is a proper subset of the S-bit closed set $\mathrm{Forb}(P_1, \ldots, P_k)$. Take a minimum cardinality SP order Q in $\mathrm{Forb}(P_1, \ldots, P_k)$ that is not in X. Then Q has at least two elements by choice of X. Since Q is an SP order, it follows that Q is a chain or antichain sum.

If Q is an antichain sum, then we may write $Q = Q_1 \oplus Q_2$, where Q_1 and Q_2 each have fewer elements than Q. Since Q is a minimum size partial order in $\mathrm{Forb}(P_1, \ldots, P_k) - X$ by hypothesis, we see that Q_1 and Q_2 are in X. Since X is $(I, \leq_I, f)$-bit closed for $(I, \leq_I, f)$ the two point antichain R_A with both points labeled R, it follows that the antichain sum of two orders in X is in X as well. In particular, Q is in X, contrary to hypothesis. This contradiction shows that Q can not be an antichain sum.

Since Q is not an antichain sum, Q must be a chain sum $Q = Q_1 \prec Q_2$. By choice of Q as minimal, we know that Q_1 and Q_2 are in X. For each i, since $Q_1 \prec Q_2$ is in $\mathrm{Forb}(P_i) = L(\mathrm{BS}(P_i) \cup \{R_A\})$, we know there is a two point chain bit B_i in $\mathrm{BS}(P_i)$ such that Q_1 is in $\mathrm{Bottom}(B_i)$ and Q_2 is in $\mathrm{Top}(B_i)$. Define the chain bit choice function c for $(P_1, \ldots, P_k)$ by letting $c(P_i) = B_i$ for each i. Then Q_1 is in $\bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i))$ and Q_2 is in $\bigcap_{1 \leq i \leq k} \mathrm{Top}(c(P_i))$. Moreover, Q_1 and Q_2 are in $\mathrm{Forb}(P_1, \ldots, P_k)$ and

$$\bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i)) \prec \bigcap_{1 \leq i \leq k} \mathrm{Bottom}(c(P_i))$$

is in $\mathrm{BS}(P_1, \ldots, P_k)$. It follows that $Q = Q_1 \prec Q_2$ is in $\mathrm{Forb}(P_1, \ldots, P_k)$, contrary to hypothesis. This contradiction completes the proof.

We now move onto excluding sets of antichain sums. As a motivating example, we may wish to compute $\mathrm{Forb}(P_1 \oplus P_2, P_2 \oplus P_3)$. We would then let Γ be the family of subsets of $\{1, 2, 3\}$ consisting of $\{1, 2\}$ and $\{2, 3\}$ and think of $\mathrm{Forb}(P_1 \oplus P_2, P_2 \oplus P_3)$ as

$$\bigcap_{F \in \Gamma} \mathrm{Forb}\left(\bigoplus_{i \in F} P_i\right).$$

This example motivates us to define, given a sequence $P_1, \ldots, P_k$ of SP orders and a family Γ of nonempty subsets of $\{1, \ldots, k\}$, the lower ideal

$$\mathrm{Forb}(\Gamma; P_1, \ldots, P_k) := \bigcap_{F \in \Gamma} \mathrm{Forb}\left(\bigoplus_{i \in F} P_i\right).$$

We need several definitions. A *splitting* of a set X is an ordered pair (A, B) such that the sets A and B partition X. We denote the set of splittings of X by $\mathrm{spl}(X)$. A *splitting function* for X is a function $h : \mathrm{spl}(X) \to \{1, 2\}$.

Let Γ be a family of subsets of $\{1,\ldots,k\}$. An *antichain bit choice function*, or ABCF, for Γ is a function g with domain Γ such that $g_F := g(F)$ is a splitting function for F for each set F in Γ. We define the left cell ideal set $\mathrm{lcis}(g)$ of g as the set of all pairs (A,F) such that F is in Γ with $A \subseteq F$ and $g_F(A, F-A) = 1$. The right cell ideal set $\mathrm{rcis}(g)$ is defined similarly but with $g_F(A, F-A) = 2$.

We define the left cell label $\mathrm{lcl}(g; P_1,\ldots,P_k)$ as the lower ideal

$$\mathrm{lcl}(g; P_1,\ldots,P_k) := \mathrm{Forb}(\Gamma; P_1,\ldots,P_k) \cap \bigcap_{(A,F)\in \mathrm{lcis}(g)} \mathrm{Forb}\left(\bigoplus_{i\in A} P_i\right)$$

and the right cell label $\mathrm{rcl}(g; P_1,\ldots,P_k)$ as the lower ideal

$$\mathrm{rcl}(g; P_1,\ldots,P_k) := \mathrm{Forb}(\Gamma; P_1,\ldots,P_k) \cap \bigcap_{(A,F)\in \mathrm{rcis}(g)} \mathrm{Forb}\left(\bigoplus_{i\in F-A} P_i\right).$$

We now define $\mathrm{BS}(\Gamma; P_1,\ldots,P_k)$ as the set of labeled antichains that have the form

$$\mathrm{lcl}(g; P_1,\ldots,P_k) \oplus \mathrm{rcl}(g; P_1,\ldots,P_k)$$

for some ABCF g for Γ.

We need to use finest antichain partitions in the next lemma. This amounts to assuming that our summands $P_1,\ldots,P_k$ are not themselves antichain sums.

Lemma 18. *Let $k \geq 1$. If the SP orders $P_1,\ldots,P_k$ are not antichain sums, then*

$$\mathit{Forb}(\Gamma; P_1,\ldots,P_k) = L(\mathit{BS}(\Gamma; P_1,\ldots,P_k) \cup \{R_C\}).$$

Proof. Let $S = \mathrm{BS}(\Gamma; P_1,\ldots,P_k) \cup \{R_C\}$. We must show that $\mathrm{Forb}(\Gamma; P_1,\ldots,P_k)$ is the S-bit closure of the doubleton containing the empty and one point partial orders. Since $\mathrm{Forb}(\Gamma; P_1,\ldots,P_k)$ trivially contains the empty and one point partial orders, it is enough to show that $\mathrm{Forb}(\Gamma; P_1,\ldots,P_k)$ is S-bit closed and that every S-bit closed set containing the empty and one point partial orders has $\mathrm{Forb}(\Gamma; P_1,\ldots,P_k)$ as a subset.

We first show that $\mathrm{Forb}(\Gamma; P_1,\ldots,P_k)$ is S-bit closed. By 2, it is enough to show that $\mathrm{Forb}(\Gamma; P_1,\ldots,P_k)$ is $(I,\leq_I,f)$-bit closed for each bit $(I,\leq_I,f)$ in S.

First, if $(I, \leq_I, f)$ is R_C, then $\mathrm{Forb}(\Gamma; P_1, \ldots, P_k)$ is $(I, \leq_I, f)$-bit closed by 6. Otherwise, by definition of S and $\mathrm{BS}(\Gamma; P_1, \ldots, P_k)$, we see that $(I, \leq_I, f)$ must have the form $\mathrm{lcl}(g; P_1, \ldots, P_k) \oplus \mathrm{rcl}(g; P_1, \ldots, P_k)$ for some ABCF g for Γ, so choose such a g. To show that $\mathrm{Forb}(\Gamma; P_1, \ldots, P_k)$ is $(I, \leq_I, f)$-bit closed for

$$(I, \leq_I, f) = \mathrm{lcl}(g; P_1, \ldots, P_k) \oplus \mathrm{rcl}(g; P_1, \ldots, P_k),$$

we must show that if Q_1 is in $\mathrm{lcl}(g; P_1, \ldots, P_k)$ and Q_2 is in $\mathrm{rcl}(g; P_1, \ldots, P_k)$ then $Q_1 \oplus Q_2$ is in $\mathrm{Forb}(\Gamma; P_1, \ldots, P_k)$. Equivalently, we may show that if $Q_1 \oplus Q_2$ is not in $\mathrm{Forb}(\Gamma; P_1, \ldots, P_k)$, then Q_1 is not in $\mathrm{lcl}(g; P_1, \ldots, P_k)$ or Q_2 is not in $\mathrm{rcl}(g; P_1, \ldots, P_k)$.

Suppose $Q_1 \oplus Q_2$ is not in

$$\mathrm{Forb}(\Gamma; P_1, \ldots, P_k) = \bigcap_{F \in \Gamma} \mathrm{Forb}\left(\bigoplus_{i \in F} P_i\right).$$

Then there is F in Γ such that $Q_1 \oplus Q_2$ is not in $\mathrm{Forb}\left(\bigoplus_{i \in F} P_i\right)$. Therefore $Q_1 \oplus Q_2$ contains a $\bigoplus_{i \in F} P_i$ suborder. We may then choose a one to one order preserving map $h : \bigoplus_{i \in F} P_i \to Q_1 \oplus Q_2$ embedding $\bigoplus_{i \in F} P_i$ into $Q_1 \oplus Q_2$. Since no P_i is an antichain sum, we know by 5 that $h(P_i)$ is contained in Q_1 or Q_2 for each i. Let $A = \{i \in F : h(P_i) \subseteq Q_1\}$. Then $F - A = \{i \in F : h(P_i) \subseteq Q_2\}$. If A is empty then $\bigoplus_{i \in F} P_i$ is a suborder of Q_2. Therefore Q_2 is not in $\mathrm{Forb}\left(\bigoplus_{i \in F} P_i\right)$, which implies Q_2 is not in

$$\bigcap_{F \in \Gamma} \mathrm{Forb}\left(\bigoplus_{i \in F} P_i\right).$$

By the definition of $\mathrm{rcl}(g; P_1, \ldots, P_k)$, this in turn implies that Q_2 is not in $\mathrm{rcl}(g; P_1, \ldots, P_k)$. This proves our claim in the case that A is empty. Similarly if $F - A$ is empty. We may thus assume that A and $F - A$ are nonempty.

Either $g_F(A, F - A) = 1$ or $g_F(A, F - A) = 2$. If $g_F(A, F - A) = 1$, then (A, F) is in $\mathrm{lcis}(g)$. Certainly $\bigoplus_{i \in A} P_i$ is not in $\mathrm{Forb}\left(\bigoplus_{i \in A} P_i\right)$, and Q_1 contains $\bigoplus_{i \in A} P_i$, which implies Q_1 is not in $\mathrm{Forb}\left(\bigoplus_{i \in A} P_i\right)$. Therefore Q_1 is not in

$$\bigcap_{(A,F) \in \mathrm{lcis}(g)} \mathrm{Forb}\left(\bigoplus_{i \in A} P_i\right).$$

By definition of $\text{lcl}(g; P_1, \ldots, P_k)$, we thus see that Q_1 is not in $\text{lcl}(g; P_1, \ldots, P_k)$. Similarly, if $g_F(A, F - A) = 2$ then Q_2 is not in $\text{rcl}(g; P_1, \ldots, P_k)$, as was to be shown. This completes the proof of the claim that $\text{Forb}(\Gamma; P_1, \ldots, P_k)$ is S-bit closed.

We must now show that every S-bit closed set containing the empty and one point partial orders has $\text{Forb}(\Gamma; P_1, \ldots, P_k)$ as a subset. Suppose not. Then the S-bit closure X of the set containing the empty and one point partial orders is a proper subset of the S-bit closed set $\text{Forb}(\Gamma; P_1, \ldots, P_k)$. So take a minimum cardinality SP order Q in $\text{Forb}(\Gamma; P_1, \ldots, P_k)$ that is not in X. Then Q has at least two elements by choice of X. Since Q is an SP order, it follows that Q is a chain or antichain sum. If Q is a chain sum $Q_1 \prec Q_2$ then Q_1 and Q_2 are in X by choice of Q as minimal. Since R_C is in S and X is S-bit closed, it then follows that $Q = Q_1 \prec Q_2$ is in X, contrary to hypothesis. This contradiction shows that Q is an antichain sum.

We write $Q = Q_1 \oplus Q_2$. We wish to get a contradiction in this case as well by showing in fact that Q is in X. Since Q_1 and Q_2 are in X by minimality of Q, and since X is $(I, \leq_I, f)$-bit closed for

$$(I, \leq_I, f) = \text{lcl}(g; P_1, \ldots, P_k) \oplus \text{lcl}(g; P_1, \ldots, P_k),$$

we see it is enough to show there is an ABCF g for Γ such that Q_1 is in $\text{lcl}(g; P_1, \ldots, P_k)$ and Q_2 is in $\text{rcl}(g; P_1, \ldots, P_k)$. Since Q is in the lower ideal $\text{Forb}(\Gamma; P_1, \ldots, P_k)$, the suborders Q_1 and Q_2 are in $\text{Forb}(\Gamma; P_1, \ldots, P_k)$ as well. By definition of $\text{lcl}(g; P_1, \ldots, P_k)$ and $\text{rcl}(g; P_1, \ldots, P_k)$, it is therefore enough to exhibit an ABCF g for Γ such that Q_1 is in

$$\bigcap_{(A,F) \in \text{lcis}(g)} \text{Forb}\left(\bigoplus_{i \in A} P_i\right)$$

and Q_2 is in

$$\bigcap_{(A,F) \in \text{lcis}(g)} \text{Forb}\left(\bigoplus_{i \in F-A} P_i\right).$$

Choose F in Γ. Since $Q_1 \oplus Q_2$ is in $\text{Forb}(\Gamma; P_1, \ldots, P_k)$, we see that $Q_1 \oplus Q_2$ forbids $\bigoplus_{i \in F} P_i$. Therefore for each splitting (A, B) of F, the SP order Q_1 must

forbid $\bigoplus_{i \in A} P_i$ or Q_2 must forbid $\bigoplus_{i \in B} P_i$. Consider the ABCF g for Γ such that for each F in Γ and each splitting (A, B) of F, we have $g_F(A, B) = 1$ if Q_1 forbids $\bigoplus_{i \in A} P_i$ and $g_F(A, B) = 2$ otherwise.

To show that Q_1 is in

$$\bigcap_{(A,F) \in \text{lcis}(g)} \text{Forb}\left(\bigoplus_{i \in A} P_i\right),$$

it is enough to show that Q_1 is in Forb $\left(\bigoplus_{i \in A} P_i\right)$ for each F in Γ and each nonempty $A \subseteq F$ such that $g_F(A, F - A) = 1$. This is immediate from the definition of g_F. Similarly, it follows immediately from the definition of g_F that Q_2 is in

$$\bigcap_{(A,F) \in \text{lcis}(g)} \text{Forb}\left(\bigoplus_{i \in F - A} P_i\right).$$

This completes the proof of the lemma.

Lemma 19. *If A and B are nonempty sets of chain sums and antichain sums, respectively, then Forb$(A \cup B) = L(BS(A) \cup BS(B))$.*

Proof. We know that Forb(A) is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in BS(A). We also know by 5 that Forb(A) is closed under arbitrary antichain sums, and since each bit in BS(B) is an antichain, we see that Forb(A) is $(I, \leq_I, f)$-bit closed for each $(I, \leq_I, f)$ bit in BS(B). Therefore Forb(A) is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in BS$(A) \cup$BS(B). By similar reasoning, Forb(B) is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in BS$(A) \cup$ BS(B) as well. This implies that Forb$(A \cup B) =$ Forb$(A) \cap$ Forb(B) is $(I, \leq_I, f)$-bit closed for each bit $(I, \leq_I, f)$ in BS$(A) \cup$BS(B), and hence Forb$(A \cup B)$ is BS$(A) \cup$BS(B) closed. Therefore $L($BS$(A) \cup$ BS$(B)) \subseteq$ Forb$(A \cup B)$.

If Forb$(A \cup B) = L($BS$(A) \cup$ BS$(B))$, we are done. Suppose not. Then $L($BS$(A) \cup$ BS$(B))$ is a proper subset of Forb$(A \cup B)$. Choose a minimum cardinality SP order Q in Forb$(A \cup B)$ that is not in $L($BS$(A) \cup$BS$(B))$. Since Q has at least two points, Q is a chain sum or an antichain sum. We assume that Q is a chain sum. The case that Q is an antichain sum is entirely similar.

Since $Q \in \text{Forb}(A \cup B) \subseteq \text{Forb}(A)$, we see that Q is in $\text{Forb}(A) = L(\text{BS}(A) \cup \{R_A\})$. Therefore there is a bit $(I, \leq_I, f)$ in $\text{BS}(A) \cup \{R_A\}$ that generates Q from proper suborders. Since Q is a chain sum, we know that Q is not an antichain sum. Therefore $(I, \leq_I, f) \neq R_A$, which implies $(I, \leq_I, f)$ is in $\text{BS}(A)$. In particular, the $\text{BS}(A) \cup \text{BS}(B)$-bit closure of the set of proper suborders of Q contains Q. Since each proper suborder of Q is in $L(\text{BS}(A) \cup \text{BS}(B))$ and $L(\text{BS}(A) \cup \text{BS}(B))$ is $\text{BS}(A) \cup \text{BS}(B)$-bit closed, we see that Q is in $L(\text{BS}(A) \cup \text{BS}(B))$, contrary to assumption. This contradiction completes the proof.

5. The Main Theorem

Theorem 20. *There is a structural description for each nontrivial proper lower ideal L.*

Proof. The proper lower ideal L is described by a finite list of forbidden suborders. That list either consists of one chain sum, multiple chain sums, multiple antichain sums, or both chain and antichain sums. We thus use 14, 17, 18, or 19, respectively to obtain a set S of bits generating L. Each label of a partial order in S is either the symbol R or is an ideal properly contained in L. For properly contained ideals, we repeat this procedure recursively. We thus obtain a finitely branching tree representing this construction. By the fact that SP orders are better quasi ordered under the suborder relation [8], it follows that there is no infinite descending sequence of lower ideals of SP orders. Therefore this construction tree is a finitely branching tree with no infinite branch, which is finite by König's Lemma. This completes the proof.

We stress that this theorem is not just theoretical; it can be applied by hand in practice to obtain specific structure theorems quickly. As one example, we characterize the diamond free SP orders. The diamond is the unique poset on points a, b, c, d such that $a < b < d$, $a < c < d$, and b and c are incomparable. An SP order is called diamond free if there is no diamond suborder. A (partial order theoretic) tree is a poset such that for each x, there are no incomparable elements less than x. A forest is tree or an antichain sum of trees. An upside

down tree (forest) is a poset such that the reverse order is a tree (forest). A forest on top of an upside down forest is a chain sum of a forest and upside down forest with the outer poset a two point chain, the top poset a forest, and the bottom poset an upside down forest. With these definitions, the reader may use the results of this paper to quickly prove the following corollary.

Corollary 21. *A finite SP order is diamond free iff it has the form*

$$\bigoplus_{\leq_I} P_i,$$

where $(I, \leq_I)$ *is an antichain and* P_i *is a forest on top of an upside down forest for each* i.

Note that the structural descriptions for ideals are not at all in general unique. Our procedure simply finds one of them. The one found may in fact have redundant rules. Note also that since lemmas 14, 17, 18, and 19, only involve the two point chain and antichain R_A and R_C, it follows that each lower ideal has a structural description only involving two point posets at any depth. At least to the author, this fact was initially surprising.

6. Acknowledgements

I thank Yared Nigussie for teaching me the mathematics [4]. The deeper understanding thus obtained by the author made this paper possible.
